# Confronting the winds: orientation and flight behaviour of roosting swifts, Apus apus 

Johan Bäckman* and Thomas Alerstam<br>Department of Animal Ecology, Ecology Building, Lund University, SE-22362 Lund, Sweden

#### Abstract

Swifts, Apus apus, spend the night aloft and this 0 ers an opportunity to test the degree of adaptability of bird orientation and fight to dijerent ecological situations. We predicted the swifts' behaviour by assuming that they are adapted to minimize energy expenditure during the nocturnal fight and during a compensatory homing fight if they become displaced by wind. We tested the predictions by recording the swifts' altitudes, speeds and directions under di; erent wind conditions with tracking radar; we found an agreement between predictions and observations for orientation behaviour, but not for altitude and speed regulation. The swifts orientated consistently into the head wind, with angular concentration increasing with increasing wind speed. However, contrary to our predictions, they did not select altitudes with slow or moderate winds, nor did they increase their airspeed distinctly when $£$ ying into strong head winds. A possible explanation is that their head-wind orientation is sux cient to keep nocturnal displacement from their home area within tolerable limits, leaving fight altitude to be determined by other factors (correlated with temperature), and airsp eed to show only a marginal increase in trong winds. The swifts were often moving 'backwards', heading straight into the wind but being overpowered by wind speeds exceeding their airspeed. The regular occurrence of such fights is probably uniquely associated with the swifts' remarkable habit of roosting on the wing.

Keywords: bird orientation; bird fight; wind drift; radar tracking

## 1. INTRODUCTION

Swifts, Apus apus, have a peculiar way of spending the night. T hey climb at dusk to high altitudes, $1000 \wedge 3000 \mathrm{~m}$ above ground level, where they $£ y$ during the dark hours before returning to their breeding colonies early in the morning (Lack 1956). This remarkable behaviour has been established by the teld, telescope, aircraft and radar evidence rep orted mainly by Weitnauer (1952, 1954, 1960). Flight altitudes have also been measured by altimeters pasted on the swifts' backs (Gustafson et al. 1977). It is mainly one-year-old immature birds that spend the night aloft but at the end of the breeding season adult birds also take part in nocturnal fights (Weitnauer 1954, 1960). However, in poor weather this regular habit of local nocturnal fying is temporarily interrupted and the swifts may set out on extensive weather movements (K oskimies 1950, Lack 1956).
We expect that swifts behave quite dijerently during nocturnal fights compared with foraging or migration fights because of fundamental di $i$ erences in optimization criteria (H edenstrî m \& A lerstam 1995; cf. 1/2). H owever, more advanced adaptive behaviours may be constrained by a lack of necessary cues in the darkness at high altitudes or by a reduced level of alertness if the swifts, in some sense, sleep during these fights (L ack 1956).
Swifts on nocturnal fights were recorded, using tracking radar, by Bruderer \& Weitnauer (1972). They reported that the swifts were fying at distinctly slower airspeeds, on average $6.5 \mathrm{~m} \mathrm{~s}^{-1}$, than during presumed migratory fights (mean of $11 \mathrm{~m} \mathrm{~s}^{-1}$ ) and low-level diurnal fights (ca. $16 \mathrm{~m} \mathrm{~s}^{-1}$, Oehme 1968). They suggested that during nocturnal fights the swifts $£ y$ at the minimum power speed, to minimize energy consumption per unit
time, while during migration they $£ y$ at the maximum range speed, to minimize energy consumption per unit distance covered (Pennycuick 1969, 1975, 1989).
In this paper we further develop predictions about the swifts' altitudes, fight speeds and orientation during their nocturnal fights in relation to winds, and test these predictions using detailed tracking-radar observations.

## 2. PREDICTIONS

At their high nocturnal altitudes swifts are very exposed to the $e_{i}$ ects of the wind. We expect them to behave in such a way as to avoid extensive dislocation and to minimize total energy consumption during the night.
Flapping fight power, $P$, is a $U$-shaped function of fight velocity (airspeed), $V$, where $V_{\mathrm{mp}}$ is the characteristic speed associated with minimum power and $V_{\mathrm{mr}}$ is the speed associated with minimum energy per unit of distance covered (e.g. Pennycuick 1969, 1975, 1989; Tucker 1973; Rayner 1979, 1999). While $V_{\text {mp }}$ is independent of wind, $V_{\mathrm{mr}}$ is a function of wind direction and speed because the distance covered relative to the ground is determined by the ground speed, which in turn is determined by the bird's fight vector and the wind vector (Pennycuick 1975; L iechti et al. 1994). We designate $V_{\mathrm{mr}}(0)$ as the maximum range speed in still air, and $V_{\text {mr }}(w)$ and $V_{\mathrm{mr}}(W)$ as the corresponding speeds in head winds of speeds $w$ and $W$, respectively, where $0 \leqslant w \leqslant W$. Since we are considering only head winds, $V_{\mathrm{mp}}<V_{\mathrm{mr}}(0) \leqslant V_{\mathrm{mr}}(w)$ $\leqslant V_{\mathrm{mr}}(W)$. The head-wind speeds $W$ and $w$ refer to the wind conditions during the swifts' high-altitude nocturnal fight and low-altitude homing fight, respectively.
There are signidcant uncertainties $a_{i}$ ecting the aerodynamic theory of bird fight, making quantitative predictions of fight speeds provisional. For the swift (body mass of 0.041 kg ; wing span of 0.45 m ; aspect ratio
of 13.2 ), predicted $V_{\mathrm{mp}}$ is $7.3 \mathrm{~m} \mathrm{~s}^{-1}$ and $V_{\mathrm{mr}}(0)$ is $12.4 \mathrm{~m} \mathrm{~s}^{-1}$ at sea-level standard air density ( $1.23 \mathrm{~kg} \mathrm{~m}^{-3}$ ), according to the revised fight mechanical program described by Pennycuick (1999). Our derivations and tests are not dependent on the precise values of these speeds (A lerstam 2000). For an ideal bird sensu Pennycuick (1975), $V_{\mathrm{mr}}(0)$ is expected to exceed $V_{\text {mp }}$ by a factor of 1.32 .

If swifts are displaced by the wind during nocturnal high-altitude fights, we expect them to make compensatory homing fights in the early morning. We assume that they then encounter a reduced wind speed by travelling at a lower altitude, where wind speeds are usually lower than the high-altitude geostrophic wind speeds. Given $W$ as the wind speed during the nocturnal high-altitude fight and $w$ as the head-wind speed during a possible homing fight, we distinguish three possible situations.

## (a) Case $A$ : $W \leqslant V_{m p}$

If $W \leqslant V_{\mathrm{mp}}$ then the swifts are expected to $£ \mathrm{y}$ at $V_{\mathrm{mp}}$ and remain stationary by varying their orientation around the head-wind direction. T his variation in orientation may be performed in dii erent ways (shifting between two or more courses or gradually changing orientation within a sector centred on the head-wind direction). The swifts' heading directions should be very variable around a mean direction that coincides with the head-wind direction (the slower the wind speed, the higher scatter in heading directions). Resulting track directions are expected to show an even higher scatter than the heading directions, relative to the wind direction.
(b) Case B: $V_{m p} \leqslant W \leqslant V_{m r}(w)$

If $V_{\mathrm{mp}} \leqslant W \leqslant V_{\mathrm{mr}}(w)$ then the swifts are expected to $£ \mathrm{y}$ at an airspeed equal to the wind speed and maintain position by heading straight into the wind. Ground speeds will be low, approaching zero in the ideal situation, and track directions are expected to show random variation relative to the wind direction. In this case, the swifts increase their airspeed above $V_{\mathrm{mp}}$ to match the wind speed. It is the expected head-wind speed, $w$, during the eventual homing fight that determines the maximum wind speed that the swifts should be prepared to match to remain stationary during the nocturnal fight rather than allowing themselves to be displaced by wind (as in C ase C, $1 / 2(\mathrm{c})$ ). If the swifts would not expect any wind reduction during the homing fight compared with the nocturnal fight ( $w=W$ ), they are expected to match the wind speed up to the maximum speed that their power capacity allows (because $\left.V_{\mathrm{mr}}(W)>W\right)$. If, on the other hand, they can make the homing fight completely sheltered from the wind, they will not increase their airspeed during the nocturnal fight beyond $V_{\mathrm{mr}}(0)$.

## (c) Case $C: W>V_{m r}(w)$

If $W>V_{\mathrm{mr}}(w)$ then the swifts are expected to $£ y$ at an airspeed of $V_{\mathrm{mr}}(w)$, heading straight into the wind. By doing so, they will be overpowered by the wind (with speed $W$ ) and carried backwards along track directions in the downwind direction. The displacement during the night will be compensated by a homing fight at airspeed $V_{\mathrm{mr}}(w)$ into a wind of speed w. This behaviour is associated with minimum energy costs according to the following derivation.

Let $V_{1}$ and $V_{2}$ be the airspeeds of the swifts during the high-altitude nocturnal fight into a wind speed of $W$ ( $W \geqslant V_{1}$ ) and during the homing fight into a wind speed of $w\left(w<V_{2}\right)$, respectively. T he displacement distance, $D$, during nocturnal-fight time, $t_{1}$, requiring homing-fight time, $t_{2}$, will be

$$
\begin{equation*}
D=\left(W-V_{1}\right) t_{1}=\left(V_{2}-w\right) t_{2} \tag{1}
\end{equation*}
$$

The total energy consumption, $E$, for the nocturnal and homing fights will be
$E=P\left(V_{1}\right) t_{1}+P\left(V_{2}\right) t_{2}$,
where $P$ is a function of $V$ according to the $£$ apping fight power curve. Inserting equation (1) into equation (2) gives
$E=t_{1}\left[P\left(V_{1}\right)+P\left(V_{2}\right) \frac{\left(W-V_{1}\right)}{\left(V_{2}-w\right)}\right]$.
Taking the partial derivative of $E$ with respect to $V_{2}$ and solving for minimum $E$ shows that the optimal $V_{2}$ is independent of $V_{1}$ and equal to $V_{m r}(w)$. Solving for the optimal $V_{1}$ in the same way shows that $V_{1}$ depends on $V_{2}$. Given that the optimal $V_{2}$ is equal to $V_{m r}(w)$, the optimal $V_{1}$ also equals $V_{\mathrm{mr}}(w)$. With $V_{1}=V_{2}=V_{\mathrm{mr}}(w)$ the energy consumption becomes
$E_{\text {min }}=t_{1} P\left(V_{\mathrm{mr}}(w)\right) \frac{(W-w)}{\left(V_{\mathrm{mr}}(w)-w\right)}$.
It can be easily shown that $E_{\text {min }}$ falls below the total energy consumption for a stationary fight into the wind at speed $W$, under the conditions of a convex power function $P(V)$ with $W>V_{\mathrm{mr}}(w)$.

We thus predict that swifts will behave in the following ways with respect to fight altitude, speeds and orientation if they are adapted to minimize total energy consumption under $\mathrm{di}_{\mathrm{i}}$ erent wind conditions during their nocturnal fights.
(i) A ltitude. The swifts are exp ected to prefer nocturnalfight altitudes with wind speeds slower than or equal to $V_{m p}$. If there is no wind, we expect the swifts to $£ y$ at low altitudes because fight power increases with altitude. Flight power is proportional to (air density) ${ }^{-1 / 2}$ for an ideal bird, sensu Pennycuick (1975). This corresp onds to a $5 \%$ increase in fight power per 1000 m increase in altitude in the standard atmosphere. However, this eject of air density on fight economy is small in comparison to the potential costs of strong winds causing longdistance displacement. Hence, we expect the swifts to primarily avoid altitudes with wind speeds exceeding $V_{\mathrm{mp}}$ ( $V_{\mathrm{mp}}$ also increases with altitude at about the same proportional rate as fight power; Pennycuick 1975).
(ii) Flight speed. The swifts are expected to $£ y$ at a constant airspeed of $V_{\mathrm{mp}}$ up to wind speeds of $W=V_{\mathrm{mp}}$. At higher wind speeds they are expected to increase their airspeed to exactly match the wind speed, up to a threshold wind speed of $W=V_{\mathrm{mr}}(w)$, above which they will not increase their airspeed any further. Ground speeds are expected to be lowest, close to zero, in the wind-speed interval

$V_{\mathrm{mp}} \leqslant W \leqslant V_{\mathrm{mr}}(w)$, when the swifts are expected to remain stationary by $£$ ying straight into the wind with an airsp eed equal to the wind speed.
(iii) Orientation. The mean heading direction is expected to coincide with the head-wind direction at all wind speeds. T he scatter of headings will be substantial at low wind speeds but will decrease with increasing wind speed. At wind speeds of $W \geqslant V_{\mathrm{mp}}$ the swifts are expected to orientate within a very narrow sector straight into the wind. Track directions will show a very wide scatter at wind speeds below $V_{m r}(w)$, when the swifts will remain in their local area during the night. However, at higher wind speeds track directions are expected to be concentrated in the downwind direction, as the swifts are carried away by the wind.

## 3. METHODS

We used tracking radar (X -band, 200 kW peak power, $0.25 \mu \mathrm{~s}$ pulse duration, 504 H z pulse rep eat frequency, $1.5^{\circ}$ pencil beam width, antenna 91.5 m above sea level), permanently situated on the roof of the E cology Building in Lund ( $55^{\circ} 42^{\prime} \mathrm{N}, 13^{\circ} 12^{\prime} \mathrm{E}$ ), to record nocturnally fying swifts between 4 July 1999 and 5 August 1999. R adar echoes of swifts are easily distinguished from other birds due to their characteristic signature. We used the following cues to classify a target as a swift: $\downarrow$ rst, the wing beats are slower than for all other small birds we expected to encounter; second, the sequence of wing-beat phases and resting phases is quite speci\$c; and, third, the signal amplitude often changes rapidly when a gliding swift tilts( Bruderer \& Weitnauer 1972). In addition, we recorded the echo signals for a sample of targets considered to be swifts, and analysed the wing-beat frequency. The average wing-beat frequency for these 21 sample individuals ranged from 7.0 to 8.3 Hz with a mean of 7.6 Hz , which is in agreement with earlier records of wing-beat frequencies for swifts during nocturnal fights ( $6 \wedge 8 \mathrm{~Hz}$ recorded by Bruderer \& Weitnauer (1972)).

During radar operation, which took place between 22.00 and 04.00 Universal Time Coordinated (UTC) ( $21.00{ }^{\circ} 03.00$ local normal time), we searched elevations between 5 and $40^{\circ}$ to 4 nd targets at di $i_{i}$ erent altitudes. We concentrated our radar search in azimuth sectors with minimal disturbance from ground echoes and, normally, at ranges of $2^{\wedge} 8 \mathrm{~km}$ from the radar.

Figure 1. Distribution of altitudes ( $m$ above sea level) for swiftstracked by radar during nocturnal $£$ ights.

O nly targets considered to be single birds were tracked. The durations of trackings used for further analysis were at least 30 s but no longer than 300 s . Azimuth, elevation and range, as registered by the radar in automatic-tracking mode, were transferred to a computer every 2 s . Horizontal and vertical coordinates were then calculated. The position data were averaged from $\$$ ve successive readings and the resulting 10 s intervals were used for calculations of speed and direction. To collect information about the wind direction and speed at the altitudes at which the birds were fying, we released and tracked helium\&lled balloons at ca. 2 h intervals.

Airspeed and heading for each swift were calculated by vector subtraction of the wind velocity (at the proper altitude) from the bird's fight track. Altitudes refer to the height above sea level. Values for altitude, speed and direction were averaged over all 10 s intervals for each tracking and used in further analysis. Calculations of mean directions, mean vector lengths $(r)$ and circular statistics were performed according to Batschelet (1981). Other statistical calculations were performed using SPSS v. 8.0 (SPSS, Inc., Chicago, IL, USA). We have mainly used the true airspeed in our analyses, but we also calculated the equivalent airspeed, $V_{\mathrm{e}}$, (airspeed corrected to standard sea-level air density, $1.23 \mathrm{~kg} \mathrm{~m}^{-3}$ ) by taking the altitude and barometric pressure into account according to Pennycuick (1999). Barometric pressures and temperatures were obtained from Falsterbo weather station (sea-level data) and

Figure 2. Distribution of ( $a$ ) ground speeds, ( $b$ ) air speeds and (c) wind speeds for swifts tracked by radar during nocturnal fights.
from Copenhagen (radiosonde measurements) at 22.00 and 23.00 UTC, respectively; both places are within 50 km of our study site.

## 4. RESULTS

Tracking-radar data were collected on 18 nights and a total of 224 tracks of targets classiфed as single swifts were recorded. On 14 nights the sky was clear, three nights were overcast (high clouds) and on one night there were thunderclouds. T he means and standard deviations of the altitudes and speeds for the total data set, and for swifts $£ y$ ying in weak, intermediate and strong winds, are given in table 1.
(a) Altitude

M ore than $80 \%$ of all tracked swifts were $£ y$ ing at altitudes between 1000 and 2200 m ( $\$$ gure 1), the mean altitude being 1683 m . Swifts dijered in their choice of altitudes between nights, and the between-night variation in altitude was highly signiфcant (one-way ANOVA, $F_{16,206}=3.37, p<0.001$ ). To test the prediction that the swifts prefer altitudes with wind speeds slower than or

Figure 3. (a) Airsp eed of swifts in relation to wind speed. The regression line has intercept $8.4 \mathrm{~m} \mathrm{~s}^{-1}$ and slope e 0.11 (correlation coex cient $=0.21, p<0.01$ ). (b) G round speed of swifts in relation to wind speed. Swifts $£$ ying with a constant airspeed of $9 \mathrm{~m} \mathrm{~s}^{-1}$ would have the ground speeds shown by the upper line with due tailwinds and those shown by the V-shaped lower line with due head winds(travel in the forward direction at wind speeds under $9 \mathrm{~m} \mathrm{~s}^{-1}$ and in the backward direction at wind speeds over $9 \mathrm{~m} \mathrm{~s}^{-1}$ ). The curve shows a least-square $\phi t$ of a quadratic function to the observed data ( $n o$ signi申cant imp rovements in $\downarrow t$ with higher-order polynomials).
equal to $V_{\text {mp }}$, we performed the following calculations. For each wind prodle (wind speeds at dijerent altitudes) associated with tracks of swifts, we extracted the minimum and maximum wind speeds in the height interval $900^{\wedge} 2400 \mathrm{~m}$, and calculated the average of these two speeds. We then calculated the mean deviation of the wind speeds experienced by the swifts from this average wind speed for each wind prodle with two or more trackings of swifts ( $n=29$ wind proфles). The average wind speed ranged from 3 to $15 \mathrm{~m} \mathrm{~s}^{-1}$ on these dij erent nights, and we expected the swifts to select altitudes with belowaverage wind speeds to an increasing degree with increasing mean wind speed. However, contrary to our prediction, the nightly mean deviations of the wind speeds experienced by the swifts from the average wind speed in the $900^{\wedge} 2400 \mathrm{~m}$ altitude interval showed a similar pattern on nights with weak winds (for 15 wind proфles with mean wind speed $3^{\wedge} 7.5 \mathrm{~ms}^{-1}$ the mean deviation was positive in six cases and negative in nine cases) to the pattern on nights with strong winds (corresponding data for 14 wind procles with mean wind speed $7.5^{\wedge} 15 \mathrm{~m} \mathrm{~s}^{-1}$ showed positive deviations in tve cases and negative deviations in nine cases). There was no statistically signiфcant correlation between mean deviation and average wind speed ( $K$ endall rank correlation, $\tau=0.042$, $n=29, p \gg 0.05$ ).

(b) Speed

The distributions of airsp eeds, ground sp eeds and wind speeds are presented in tgure 2. Airspeeds were more concentrated than both ground speeds and wind speeds and showed a narrow scatter around the mean of $9.3 \mathrm{~m} \mathrm{~s}^{-1}$ (s.d. $=2.3 \mathrm{~m} \mathrm{~s}^{-1}$ ). M ean equivalent airspeed was $8.5 \mathrm{~m} \mathrm{~s}^{-1}$ (s.d. $=2.2 \mathrm{~m} \mathrm{~s}^{-1}$ ) (table 1). The vast majority of swifts were fying into head winds (cf. $1 / 2(\mathrm{~A})$ ) and there was a signi申cant positive correlation between airspeed and wind speed ( $F_{1,223}=10.598, p<0.01$ ). H owever, the rate of increase was very low, $c a .0 .1 \mathrm{~m} \mathrm{~s}^{-1}$ increase in airspeed per $1 \mathrm{~ms}^{-1}$ increase in wind speed (\$gure $3 a$ ), which is lower than predicted. In contrast, ground speed did not increase with increasing wind speed, but was lowest at intermediate wind speeds (table 1 and $\phi$ gure $3 b$ ). This is a consequence of the fact that most swifts were £ying into head winds, travelling forwards at low wind speeds, being almost stationary when the wind speed was similar to the airspeed, and being blown backwards at increasing rates by strong head winds exceeding the airspeed. M ean vertical speed $\left(V_{z}\right)$ was close to zero $\left(-0.03 \mathrm{~m} \mathrm{~s}^{-1}\right.$, s.d. $\left.=0.48 \mathrm{~m} \mathrm{~s}^{-1}\right)$ and did not dijer between trackings with dij erent wind speeds (table 1). This could indicate that the swifts made only minor changes in altitude. A nother possibility is that they did change altitude, but climbed and descended in equal fractions. The average value of absolute $V_{z}\left(0.31 \mathrm{~m} \mathrm{~s}^{-1}\right.$, s.d. $=0.34 \mathrm{~m} \mathrm{~s}^{-1}$ ) indicates that this was the case to only a small degree (during dusk ascent, swifts climb with an average $V_{\mathrm{z}}$ of $1.3 \mathrm{~m} \mathrm{~s}^{-1}$, H edenstrî m \& A lerstam 1992).

## (c) Orientation

The geographical compass courses of the swifts were scattered in all directions, with the mean bearing and vector length being $168^{\circ}$ and $r=0.20$, respectively, for
track directions, and $216^{\circ}$ and $r=0.43$, respectively, for heading directions. Wind direction was also very variable, with a mean direction of $222^{\circ}$ and a mean vector length of $r=0.24$. A more meaningful pattern emerged when considering the swifts' fight directions relative to the wind direction. If the angular dijerence between the heading direction, $H$, and the wind direction, $D$, is zero, then the bird is $£ y$ ing exactly into the wind. Our results show clearly that the average $H-D$ is close to zero and that the scatter around zero decreases signiфcantly with increasing wind speed (\$gure 4). Track direction, T, relative to wind direction, does not di $i$ er signiфcantly from a uniform distribution at low and intermediate wind speeds. However, in strong winds $T-D$ app roaches $180^{\circ}$, when at the same time $H-D$ is highly concentrated towards $0^{\circ}$. This means that the swifts were heading straight into the wind but were being blown backwards by the strong wind.

## 5. DISCUSSION

The results from the radar studies are in agreement with only one out of our three predictions: the swifts orientated exactly as predicted. Their headings were directed into the wind, with a rather large scatter around the head-wind direction at low wind speeds ( $r=0.38$ ) and a much narrower scatter ( $r=0.87$ ) in strong winds (\$gure 4). Resulting track directions were randomly scattered in all directions at low and intermediate wind speeds, while in strong winds the swifts, heading straight into the wind, were transp orted backwards.

The swifts' orientation in relation to wind direction is an impressive behaviour requiring an advanced capability to estimate wind direction and speed. This makes it less likely that the swifts fail to behave in an adaptive way
with respect to fight altitude and speed, possibly because of a lack of the necessary sensory cues in darkness at high altitudes or because of a reduced responsiveness when in a nocturnal resting mode. Why then do the swifts not adjus their altitude and speed in relation to the wind conditions as predicted?

## (a) Altitude

Weitnauer (1960) suggested that thermals and ambient temperature may in£uence the altitude of swifts during their nocturnal fights. We analysed temperatures (at altitudes where the swifts were $£ y$ ing) for the swifts in our data set, and found that the average temperature experienced by the swifts ranged from 5.5 to $14.4^{\circ} \mathrm{C}$ on di i erent nights and the between-night variation was highly signi\$cant ( $F_{16,206}=12.0, p<0.001$ ). There was a signitcant correlation between mean altitude and mean temperature (correlation coed cient $=0.54, n=18$ nights, $p<0.05$ ), showing that the swifts were £ying at higher altitudes on warmer nights. We have no plausible explanation for this, but since the fights lasted for several hours it could be connected with maintenance of the water balance (K vist et al. 1998). The occurrence of insects at the high altitudes used by swifts for their nocturnal $£$ ights is normally (at least at night when there are no thermals) negligible (C. Solbreck, personal communication) making it quite improbable that aspects of foraging infuence the swifts' altitudes

## (b) Speed

The equivalent airspeed was, on average, $8.5 \mathrm{~m} \mathrm{~s}^{-1}$, being somewhat slower in weak winds (mean of $8.1 \mathrm{~m} \mathrm{~s}^{-1}$ ) than in strong winds ( $9.0 \mathrm{~m} \mathrm{~s}^{-1}$ ) (table 1). These speeds are only slightly higher than the $V_{\mathrm{mp}}$ of $7.3 \mathrm{~m} \mathrm{~s}^{-1}$ predicted by fight mechanical theory (Pennycuick 1999). Hence, it seems likely that the swifts were $£ y$ ying at or near $V_{\text {mp }}$, as expected if the energy per unit time is minimized. The true airspeed was, on average, $9.3 \mathrm{~ms}^{-1}$ (table 1), which is faster than the value of $6.5 \mathrm{~m} \mathrm{~s}^{-1}$ reported by Bruderer \& Weitnauer (1972). The reason for this discrepancy is not entirely clear, but could, at least partly, be due to $\mathrm{di}_{i}$ erences in the methods used to calculate the fight track. In our study we used 10 -s intervals for speed calculations (based on \$ve 2 -s readings), while Bruderer \& Weitnauer (1972) measured fight distances from a paper printout.

The fact that the swifts did not show any distinct increase in airspeed when fying into head winds with speeds exceeding their own airspeed indicates that they are more tolerant of nocturnal displacement than we have assumed. Swifts taking part in nocturnal fights are, to a large extent, non-breeding birds (Weitnauer 1954, 1960) and are therefore not forced to be back in the colony the next day. Perhaps the swifts can combine compensatory homing fights in the morning with foraging, with similar benetts and costs as local foraging fights close to their home colonies. If so, we have overestimated the costs of displacement by assuming that displaced swifts have to pay extra costs corresponding to the full transport costs of the homing fights, compared to swifts that are already at their home areas at daybreak. Even if displacement costs are smaller than assumed, they are probably not negligible. If they were, it would not matter in which directions
the swifts were fying relative to wind and we would not have observed an orientation into the head-w ind direction.

Assuming that there is a small but signiфcant extra energy cost, $k$, proportional to the distance displaced (this cost may be related to the probability of displacement over less-suitable foraging areas, such as the sea or unp roductive habitat), the energy consumption, $E$, for the nocturnal fight, including the extra cost associated with displacement, becomes (for the case where wind speed exceeds the bird's airsp eed)
$E=P\left(V_{1}\right) t_{1}+k\left(W-V_{1}\right) t_{1}$,
where $P\left(V_{1}\right)$ is power at the swift's nocturnal airspeed $\left(V_{1}\right), t_{1}$ is nocturnal-fight time and ( $W-V_{1}$ ) $t_{1}$ is displacement distance, with wind speed, $W$, greater than $V_{1}$. T his equation is analogous to equation (2) with modiqed assumptions about the costs associated with the homing fight. Solving for the optimal $V_{1}$ associated with the minimum $E$ gives the condition
$\frac{\mathrm{d} P\left(V_{1}\right)}{\mathrm{d} V_{1}}=k$.
This means that the optimal airsp eed exceeds $V_{\mathrm{mp}}$ to an increasing degree with increasing $k$ (with $k=0$, that is with no displacement costs, the optimal airspeed is $V_{\mathrm{mp}}$ ). We speculate that the slight but signiфcant increase in observed airspeed with increasing wind speed (\$gure 3a and table 1) is due to the existence of a small but signiccant distance-related cost factor for displacement as dedned above.
The swifts' orientation into the wind seems to be ei ective at keeping the displacement within tolerable limits. For example, by heading straight into a wind of $15 \mathrm{~m} \mathrm{~s}^{-1}$ with an airspeed of $9 \mathrm{~m} \mathrm{~s}^{-1}$, the resulting ground speed for the backward displacement is $6 \mathrm{~ms}^{-1}$. This corresponds to a displacement distance of 108 km during a 5 h nocturnal $£$ ight. If the swifts failed to orientate relative to the wind, their average ground speeds would be at least $15 \mathrm{~m} \mathrm{~s}^{-1}$, up to $24 \mathrm{~m} \mathrm{~s}^{-1}$ for individuals £ying with a tailwind. The latter would bring about a fourfold increase in the displacement distance ( 432 km over 5 h ), compared to the head-wind orientation.

## 6. CONCLUSION

We conclude that swifts spending the night aloft show a consistent orientation into the wind, with angular concentration increasing with increasing wind sp eed. This is the behaviour predicted if they are assumed to minimize the wind displacement and energy expenditure associated with their nocturnal fights. However, they do not select altitudes with slow or moderate winds, nor do they increase fight speed in a distinct way when fying into stronger head winds, as predicted by the same assumptions. This paradox may be explained by the fact that wind displacement involves only a small (but signi申cant) cost, much less than the transp ort cost of the compensatory homing fight. This means that the swifts' orientation behaviour keeps the displacement within tolerable limits, while the fight altitude may be determined by other factors (such as temperature) and the airspeed shows only a marginal increase in trong winds.

The nocturnal fights of swifts show a new and consp icuous feature not seen in migrating birds (when fight with tailwinds is preferred; A lerstam 1990) or in song fight (Hedenstrîm \& Alerstam 1996): the swifts are often fying 'backwards', heading straight into the wind but being overpowered by wind speeds exceeding their airspeed. The fact that they regularly spend nights aloft under such conditions, rather than using roosting sites on the ground (which is known to occur in the foliage of trees and on masts, especially among juvenile birds; Holmgren 1993), bears witness to their extraordinary quali申cations for life in the wind.

We are grateful to C.-G. Carlsson and UIf Olsson at Aerotech Telub for skilfully installing and adapting the radar, and to meteorologist Bertil Larsson for developing ex cient software for the treatment of the radar data. Weather data were obtained from the Danish M eteorological Institute (radiosonde data from Copenhagen) and the Swedish M eteorological and Hydrological Institute. We are grateful for the valuable comments of two anonymous referees. This work was supported by grants from the Swedish Natural Science Research Council.
